Abstract:

**Aims** To examine whether increasing fasting plasma glucose (FPG) levels were associated with worsening left ventricular (LV) diastolic function, independently of LV mass index (LVMI) in elderly, otherwise healthy subjects.

**Methods and results** We tested cross-sectional associations between echocardiographically determined averaged E/é ratio / diastolic function, LVMI, cardiovascular risk factors, and FPG categorized as normal (NFG), impaired (IFG), and new-onset diabetes mellitus (DM), in 483 men and 208 women aged 56-79 years without overt cardiovascular disease, who received no cardiovascular, anti-diabetic, or lipid-lowering drugs and had a preserved LV ejection fraction > 50%.

Median E/é was significantly higher among subjects with diabetes than those without (8 vs. 7; p = 0.03), as was the prevalence of grade 2 or 3 diastolic dysfunction (25% vs. 16%; p = 0.02). E/é and diastolic function were significantly associated with LVMI (p ≤ 0.002), but not FPG category, on multivariable analysis. However, interaction analyses revealed that increasing LVMI was primarily associated with worsening diastolic function (higher E/é) in subjects with FPG > 6mmol/l (β = 0.005 for IFG and DM vs. 0.001 for NFG; p = 0.02), whereas increasing systolic blood pressure was primarily associated with worsening diastolic function (higher E/é) in subjects with FPG ≤ 6.9mmol/l (β = 0.005 for NFG and 0.003 for IFG vs. -0.001 for DM; p = 0.001).

**Conclusion** Diastolic dysfunction was significantly more prevalent among patients with DM than those without. The importance of LVMI increased, but the importance of systolic blood pressure decreased with higher FPG category.
1. Introduction

Diastolic dysfunction (DD) is the inability of the cardiac myofibrils to rapidly or completely return to their resting length and is characterized by delayed active relaxation and increased left ventricular (LV) stiffness [1]. The condition is most often caused by ischemic heart disease and/or hypertension with subsequent concentric remodeling or hypertrophy of LV [2]. LV hypertrophy and DD are common findings among patients with diabetes mellitus (DM), with the presence and severity of LV DD being directly correlated to the duration of DM [3-5]. The associations are independent of concomitant hypertension and ischemic heart disease. Therefore, it seems that patients with DM are predisposed to a primary myocardial disease, diabetic cardiomyopathy, defined as ventricular dysfunction occurring in a diabetic patient, independently of a recognized cause [3].

DD in patients with DM is associated with both subsequent development of heart failure (HF) and increased mortality [4,5]. The mechanisms through which DD develops and progresses to overt HF in patients with DM are not clearly understood, but may be partially associated with increased LV mass [3]. Keeping in mind the negative results of recent clinical trials regarding the management of HF with preserved ejection fraction [6,7], a better understanding of the pathogenesis of DD is essential for development of novel therapeutic strategies that can prevent or delay this process.

LV diastolic function can be non-invasively evaluated by Doppler echocardiography, and a wide range of specific echocardiographic indicators of diastolic function exist [8]. The combination of assessing mitral annulus motion with tissue Doppler during early diastole (ê) and early passive mitral inflow velocity (E) provides an acceptable estimate of LV filling pressure, with E/ê < 8 being associated with normal filling pressure, whereas values > 12-15 are associated with elevated filling pressures. Moreover, studies have demonstrated a reduction of ê in type 2 DM and an independent correlation between increased E/ê and both glycosylated hemoglobin (HbA1c), mortality, and the risk of development of overt HF [4,5,9-12]. Therefore, the E/ê ratio may be used to detect and follow the progression of LV DD in patients with DM.

The purpose of this study was: 1) To examine whether worsening glucometabolic status was associated with worsening LV diastolic function, independently of increased LV mass index (LVMI); and 2) To identify other risk factors independently associated with worsening LV diastolic function.
2. Methods

The study was a cross-sectional study.

2.1 Study population

The study subjects were derived from the Malmö Preventive Project (MPP, 1974-1992, n = 33,346), a population-based cohort study with the aim of screening for cardiovascular risk factors, alcohol abuse, and breast cancer among inhabitants in Malmö, Sweden, born 1921-1949 [13]. A re-examination study (MPP-RES, n = 18,238) was conducted between 2002-2006, during which the participants answered a questionnaire on lifestyle, medical history, and medication. Blood pressure and pulse rate were recorded twice in the supine position after 5 minutes of rest (with the values averaged for the analyses), and height, weight, waist and hip circumferences were measured. Moreover, blood samples were drawn after overnight fasting for analysis of plasma glucose, serum lipids, and storage in a biobank. In a subsample of 1,792 individuals from MPP-RES, an echocardiography was carried out. These subjects were randomly selected from groups defined by fasting plasma glucose (FPG), with oversampling in groups of subjects with impaired fasting glucose (IFG) and DM. Both MPP and MPP-RES were approved by the Ethics Committee of Lund University, Sweden and conducted in accordance with the Declaration of Helsinki. Written informed consent was obtained from all participants.

2.2 Prevalent cardiovascular disease or diabetes mellitus

Subjects with prevalent cardiovascular disease (n = 300) and/or those on cardiovascular (n = 864), anti-diabetic (n = 329) or lipid-lowering therapy (n = 464) were excluded in the present study (total excluded n = 1029). Prevalent cardiovascular disease was defined by the International Classification of Diseases (ICD-9 and ICD-10) codes gathered from the Swedish Hospital Discharge Registry as well as local hospital and study registries and encompassed previous myocardial infarction, percutaneous coronary intervention, coronary artery bypass grafting, HF, stroke, or atrial fibrillation and/or flutter.

2.3 Glucometabolic status

The definitions of normal fasting glucose (NFG), IFG, and DM were based on the World Health Organization (WHO) criteria [14]: NFG was defined as a single FPG ≤ 6.0 mmol/L; IFG was defined as a single FPG between 6.1-6.9
mmol/L, or one measurement 7.0-11.0 mmol/L and a separate measurement ≤ 6.9 mmol/L; and new-onset DM was defined as a single FPG ≥ 11.1 mmol/L or two separate measurements ≥ 7.0 mmol/L.

2.4 Echocardiography

Echocardiography was conducted with a 3V2c transducer (Acuson Sequoia, Mountain View, CA) or an S3 transducer (Sonos 5500 Philips, Andover, MA). LV ejection fraction (LVEF) was quantified visually. LV mass calculations were based on 2-dimensional images in the parasternal long-axis view at the level of the mitral valve tips during end-diastole, using the formula recommended by the American Society of Echocardiography (ASE), and indexed for body surface area, obtaining LVMI [15]. Left atrial area (LAA) during end-systole was obtained by planimetry in the apical four-chamber view. LV diastolic function was assessed in the apical four-chamber view using transmitral pulsed Doppler flow with a 1-3 mm sample volume placed between the tips of the mitral valve leaflets (obtaining E, A, and E-wave deceleration time (DT)) and tissue Doppler imaging with the sample volume positioned within 1 cm of the septal and lateral borders of the mitral annulus (obtaining both septal and lateral é and averaging the values for the analyses). A mean of 3-5 cycles was used. The intra- and interobserver variabilities are reported elsewhere [16]. Diastolic function was graded according to the recommendations of the European Association of Echocardiography (EAE) and ASE, using age-appropriate cut-off values of septal é, lateral é, E-wave DT, E/A, and averaged E/é [8]. If septal é was ≥ 8 and/or lateral é was ≥ 10, subjects were classified as having normal diastolic function. If septal é was < 8 and lateral é was ≤ 10, subjects were classified as having DD, and the values of E-wave DT, E/A, and E/é were used for grading subjects into grade 1, 2 or 3 DD (table 1). If E/é was ≥ 9 and ≤ 12, subjects were only classified as having either grade 1 or 2 DD if the values of both E-wave DT and E/A fitted the same category. Equivocal cases, i.e. subjects who were in a transitional state between grade 1 and 2 DD with E/é ≥ 9 and ≤ 12, but E/A and E-wave DT pointing in opposite directions, were classified as undetermined DD. If E/é was > 12, subjects were classified as having either grade 2 or 3 DD. Finally, all subjects with E/é < 9 were classified as either normal (E-wave DT < 240ms and E/A ≥ 0.8) or grade 1 DD (all other subjects), even if they did not strictly fulfill the primary é criteria for normal diastolic function. Grade 2 and 3 DD were grouped together, since only one individual fulfilled the criteria for grade 3 DD. Subjects with LVEF ≤ 50% were excluded in the present study (n = 29). Moreover, 43 subjects were excluded due to missing echocardiographic variables.
2.5 Biomarkers

In the echocardiography subcohort, N-terminal prohormone of brain natriuretic peptide (NT-proBNP) was analyzed using an electrochemiluminescence immunoassay (Elecsys, Roche Diagnostics, Basel, Switzerland) at the Department of Clinical Chemistry, Akershus University Hospital, Lorenskog, Norway.

2.6 Statistical analysis

Continuous variables were summarized by means and standard deviations (approximately normally distributed variables) and medians and interquartile ranges (IQR) (non-normally distributed variables), whereas categorical variables were presented by frequencies and corresponding percentages. Group-wise comparisons were performed using one-way analysis of variance (ANOVA), Kruskal-Wallis test, and Pearson’s χ²-test or Fisher’s exact test (depending on cell frequencies), respectively. Since E/é was moderately positively skewed, the association between E/é and various risk factors was assessed by multivariable linear regression after natural log-transformation of E/é. The association between diastolic function and risk factors was assessed by ordered logistic regression. In order to define potential explanatory variables for E/é and worsening diastolic function, univariate regressions were applied on the following demographic and clinical variables: age, sex, smoking status, body mass index (BMI), waist circumference, systolic blood pressure (SBP), pulse rate, FPG category, total cholesterol, low-density lipoprotein (LDL) cholesterol, high-density lipoprotein (HDL) cholesterol, triglycerides, NT-proBNP, and LVMI. Statistically and clinically significant variables were included in the final multivariable linear and ordered logistic regression models, and stepwise subset selection was applied for adjustment of these models with an entry level of 0.2. The significance level for the univariate analyses was 5%. Analyses were carried out using IBM SPSS Statistics 22 (IBM, Armonk, New York, USA) and Stata/IC 13 (StataCorp LP, College Station, Texas, USA).

3. Results

3.1 Characteristics of the study population

The final study cohort (figure 1) comprised 691 subjects (483 men and 208 women), including 344 individuals with NFG, 240 with IFG, and 107 with new-onset DM. Subjects were middle-aged or elderly with a median age of 66 (IQR 60-70) years and mildly hypertensive with a mean SBP of 147 +/- 20 mmHg. Mean BMI was 24.0 +/- 3.2 kg/m², and values of total and LDL cholesterol were 5.9 +/- 1.0 mmol/L and 3.9 +/- 0.9 mmol/L, respectively. Median averaged E/é was 7 (IQR 6-10), and 18% (when excluding subjects with undetermined DD) had grade 2 or 3 DD. Worsening
glucometabolic status (i.e. higher FPG category) was associated with increasing BMI, waist circumference, SBP, pulse rate, triglycerides, LVMI, and LAA, and decreasing HDL cholesterol, whereas the presence of DM was associated with increased E/é, male sex, and a greater prevalence of both grade 2 or 3 DD and E/é ≥ 13. Table 2a and 2b show the baseline characteristics of the subjects categorized according to FPG category and diastolic function, respectively, whereas table 2c shows the characteristics of the subjects with undermined DD.

### 3.2 Determinants of the averaged E/é ratio

E/é was significantly higher in subjects with DM than those without (8 (IQR: 6-11) vs. 7 (IQR: 6-10), p = 0.03), Mann-Whitney U test). In univariate analyses, an increasing value of E/é was associated with higher age, BMI, SBP, total cholesterol, NT-proBNP, LVMI, and female sex. The adjusted linear regression model is presented in table 3a and included age, BMI, SBP, LVMI, and sex, whereas FPG category was forced into the model. In a separate model, E/é was significantly associated with LVMI (β = 0.004 (95% CI: 0.002 to 0.005), p < 0.0001), but not FPG category (NFG: reference; IFG: β = -0.06 (95% CI: -0.12 to -0.007), p = 0.03; DM: β = 0.05 (95% CI: - 0.03 to 0.13), p = 0.2). The same was true when subjects were subdivided into two glucometabolic categories only, i.e. DM vs. NFG or IFG. However, FPG category significantly interacted with the association between E/é and SBP (p = 0.03), NT-proBNP (p < 0.001), and LVMI (p = 0.02) (figure 2a).

### 3.3 Determinants of worsening diastolic function

Grade 2 or 3 DD was more prevalent among subjects with diabetes than those without (25% vs. 16%, p = 0.02, Pearson’s χ²-test), as was E/é ≥ 13 (15% vs. 6%, p = 0.001, Pearson’s χ²-test). In univariate analyses, worsening diastolic function was associated with higher age, BMI, NT-proBNP, LVMI, and female sex. The adjusted ordered logistic regression model is presented in table 3b and included age, LVMI, and sex, whereas FPG category was forced into the model. In a separate model, diastolic function was significantly associated with LVMI (OR = 1.02 (95% CI: 1.01 to 1.03), p < 0.0001), but not FPG category (NFG: reference; IFG: OR = 0.59 (95% CI: 0.40 to 0.86), p = 0.006; DM: OR = 1.02 (95% CI: 0.64 to 1.63), p = 0.9). Considering only DM vs. NFG or IFG yielded similar results. FPG category significantly interacted with the association between diastolic function and SBP (p = 0.03), and NT-proBNP (p = 0.005) (figure 2b).
4. Discussion

The main findings of our study were: 1) A significant greater prevalence of grade 2 or 3 DD among subjects with new-onset DM than those without; 2) A significant positive association between worsening diastolic function and increasing LVMI; 3) Significant interactions, i.e. effect modifications, between glucometabolic status and other cardiovascular risk factors, including surrogate markers of hemodynamic load, i.e. SBP, NT-proBNP, and LVMI, in the prediction of diastolic function, with increasing SBP and NT-proBNP being predominantly associated with worsening diastolic function among subjects without DM, whereas increasing LVMI showed a stronger association with worsening diastolic function (as determined by higher E/é) among patients with IFG or DM.

Prevalence measurements of asymptomatic or pre-clinical DD, i.e. DD with normal systolic function and no symptoms of HF, are not easily obtained due to differences in defining DD and HF [2]. The prevalence of pre-clinical DD in the general adult Caucasian population is estimated to be 20-30%, but only 5-10% for moderate or severe DD [17-20]. In patients with DM, the reported prevalence varies between 20-60% [5]. In accordance with the algorithm provided in the EAE-ASE recommendations, the primary steps in grading diastolic function in the present study were septal and lateral é [8]. Although this by itself could lead to an overestimation of subjects with grade 2 DD, an averaged E/é ≥ 9 was also required. Most other investigators used E/é ≥ 10 as cut-off, and the greater number of subjects with moderate or severe DD in our study may be partially explained by the fact that E/é ≥ 9 and < 10 was common (8%). Using averaged E/é ≥ 13 (the recommended cut-off for predicting increased LV filling pressure in subjects with preserved LVEF) as the sole criterion for DD yielded estimates much closer to those shown in previous similar studies.

Regarding risk factors for pre-clinical DD in subjects without overt cardiovascular comorbidities, our results generally agreed with previous findings, since increasing age, SBP, BMI, LVMI, NT-proBNP levels, DM, and female sex were all significantly associated with worsening diastolic function, at least on univariate analysis [5,17-19]. We did not find a graded effect of FPG category on DD prevalence or severity, even though IFG represented an intermediate state between NFG and DM concerning other risk factors. This complied with the Strong Heart Study, which, however, did not include E/é and only examined subjects below 40 years of age [21], but was in contrast to the Diagnostic Trial on prevalence and clinical course of diastolic dysfunction and diastolic heart failure, in which both DD prevalence and severity increased along the diabetic continuum [11]. In the latter study, however, all subjects without a history of DM underwent an oral glucose tolerance test (OGTT), and although the risk of future development of type 2 DM is the same
for individuals with either IFG or impaired glucose tolerance (IGT), the latter seems to be a better predictor of cardiovascular mortality, and perhaps pre-clinical cardiac damage as well [22]. Furthermore, subjects were required to either have risk factors for diastolic HF or manifest chronic HF, strengthening the chance of finding such associations. Our detection of a significant difference in both E/é and the prevalence of grade 2 or 3 DD between subjects with DM and those without, raises the question of whether a certain threshold level of glucose exists, at which the adverse effect on myocardial function is accelerated.

Interestingly, FPG category significantly interacted with the association between surrogate markers of hemodynamic load and diastolic function, i.e. increasing SBP and NT-proBNP were predominantly associated with worsening diastolic function among subjects without DM, whereas increasing LVMI showed a significantly stronger association with worsening diastolic function among patients with IFG or DM. Although speculative, the latter may suggest that glucose levels in the diabetic range somehow affect the myocardium by amplifying the deteriorating effects of increasing LV mass on myocardial relaxation, i.e. the presence of DM intensifies the myocardial stiffening caused by LV hypertrophy. Our findings could be explained by the following observations [23]: 1) Pathological LV hypertrophy results in decreased coronary flow reserve (CFR), and there is an association between the magnitude of CFR reduction and DD; 2) Coronary flow reserve is also decreased in patients with DM as either a direct consequence of hyperglycemia or due to insulin resistance, endothelial dysfunction, or increased sympathetic activity; 3) DM by itself is associated with increased LV mass, which may be due to microvascular damage causing myocardial damage and reactive fibrosis and/or hypertrophy.

Our results also indicate that among patients with DM, increased LVMI may have a much greater influence on myocardial stiffening than increased SBP and other traditional risk factors, which seemed to matter mainly in subjects without DM. Although this finding disagrees with previous studies showing a synergistic effect of DM and hypertension [24], an explanation may be provided by the Cardiovascular Continuum, i.e. the concept that both physiological and pathological ageing brought on by cardiovascular risk factors, e.g. DM, result in similar disturbances in LV structure and function [25-27]. In other words, impaired glucose metabolism can be considered an accelerator for physiological ageing. The subjects in the present cohort were relatively old, and the strong positive association between age and diastolic function in addition to the presumed late onset of glucometabolic disturbances could explain the lack of an association between FPG category and diastolic function on multivariable analysis. In patients with DM; however,
one would still expect the presence of DM to dominate over other traditional risk factors, which may explain the non-
significant association between SBP and diastolic function in these particular individuals. The observation that
increasing SBP was only associated with increasing E/é and worsening diastolic function in the younger half of our
study population supports this hypothesis (results not shown). In addition, the chances of finding an additive or
synergistic effect was attenuated by our exclusion of patients receiving anti-diabetic or cardiovascular medication as
well as the abovementioned old age of the subjects, whereby traditional risk factors, e.g. hypertension, may have
already exerted their effects, perhaps by having increased LV mass.

Despite the established association between DM and LV DD, the pathophysiological mechanisms by which type 2 DM
impairs myocardial function have not been fully elucidated, and other hypotheses do exist. A theoretical framework has
been proposed in which DD can be thought of as a process of different conditions, e.g. overweight, hypertension, and
DM, inducing a state of both systemic and microvascular inflammation causing cardiomyocyte hypertrophy and
stiffening through coronary microvascular endothelial dysfunction [28]. This theory, which suggests that several
independent risk factors may play a role, also fits well the described results. Looking at tables 3a and 3b and taking into
account this hypothesis, a multidisciplinary therapeutic approach aimed at both systemic and cardiovascular
comorbidities, initiated at an early stage, including lowering of blood pressure, regression of LV hypertrophy and/or
concentric LV geometry, lowering of elevated plasma glucose, weight reduction, lipid-lowering, and anti-inflammatory
therapy, e.g. with statins, may delay the progression of asymptomatic DD to overt HF.

4.1 Limitations
Although the participation rate of 72% in MPP-RES is considered high, one may still argue that the study subjects did
not represent a truly random population sample since people who agree to take part may be healthier than the general
population. 70% of the subjects in the present study were male, which may limit the applicability of the results in
females. Moreover, our exclusion of more than half of the original study population in order to get a cohort of
apparently healthy subjects in whom possible associations are not affected by medication may as mentioned earlier
introduce a selection bias. The subgroup division was based on FPG, in most cases only a single measurement. The
addition of an OGTT and/or HbA1c measurements would have been preferable, as IGT and DM defined by OGTT is
more common among women than men [22], and HbA1c provides an estimate of the average glucose levels, and
perhaps sustained myocardial affection, over a 8-12 week period [29]. The oversampling of subjects with either IFG or DM also prevented us from using FPG as a continuous variable.

The usefulness of \( e \) velocity in normal subjects may be limited, as preload increases \( e \) in these subjects [30]. Moreover, lateral E/\( e \) may be superior to septal E/\( e \) for predicting LV filling pressure in subjects with LVEF > 50%, but our choice of using averaged E/\( e \) was due to the lack of information on regional dysfunction. Also, although increased E/\( e \) is indicative of elevated LV filling pressure, it should not be used as a stand-alone parameter when drawing conclusions about LV DD. Our grading of DD could; however, have been more robust, had we also been able to incorporate the left atrial volume index [8]. Finally, the cross-sectional nature of our study prevents us from making finite inferences about causality.

5. Conclusion

In conclusion, although apparently healthy, elderly subjects with new-onset DM had higher values of averaged E/\( e \) and a greater prevalence of grade 2 or 3 DD, the associations were not independent of LVMI. However, FPG category significantly interacted positively with the association between E/\( e \) and LVMI, with LVMI predominantly being associated with higher E/\( e \) in subjects with IFG or DM.
