Abstract
Objective: To evaluate microwave thermotherapy as a treatment option for benign prostate hyperplasia (BPH) in patients with chronic retention and an indwelling catheter.

Patients and Methods: 24 unselected patients, 53–91 years old (mean age 73 years) with chronic urinary retention and an indwelling catheter were treated with ProstaLund Feedback Treatment®. Patients had had an indwelling catheter for 1–12 months prior to treatment. ProstaLund Feedback Treatment is an enhanced microwave treatment where the actual intraprostatic temperature is monitored and used to control the microwave power.

Results: 19 (80%) of the 24 patients were successfully relieved of their indwelling catheter with satisfactory peak flow, residual urine and symptom score. Treatment failed in 5 (20%) out of the 24 cases. The reasons of failure were identified in all 5 cases and indicate that the method may be less suitable in case of a median lobe or large protruding lobes into the bladder. There were no serious complications such as bleeding requiring hospital intervention, sepsis or urine incontinence. Isolated cases of urinary infection occurred.

Conclusion: The satisfying outcome of a 1-hour-long out-patient procedure for this patient category suggests that ProstaLund Feedback Treatment may be a good alternative to surgery for BPH patients with chronic retention and an indwelling catheter.

Introduction
Minimally invasive methods such as microwaves, varying forms of laser and transurethral needle ablation have all been developed in the 1990s. The underlying principle behind these methods is to coagulate prostatic adenomatous tissue by means of heat. An advantage of microwaves compared to other minimally invasive techniques is their ability to heat the whole intended treatment volume simultaneously which makes the procedure easy to carry out. Efficacy
and safety studies of microwave treatment indicate that the subjective improvements are similar to surgery, while objective improvements relating to pressure/flow are less than after surgery [1]. Recent technological development and new treatment protocols have, however, led to further improvement in treatment outcome [2]. Posttreatment morbidity of microwave thermotherapy includes a rapidly developed oedema in the prostate, and catheterisation for up to 2 weeks is usually required. Retrograde and dry ejaculation are also seen but to lesser degree than after TURP. The safety of microwave thermotherapy seems high [3], and severe complications are rare in the literature.

Many BPH patients with chronic urinary retention are old and fragile and unsuitable for TURP or open surgery because of the operation risks involved. In a retrospective US study on 218,127 Medicare patients operated between 1984 and 1990, the 30-day mortality following TURP was assessed to be 0.4% for patients aged between 65 and 69 years and 3.5% for patients 85 years and older [4]. In a recent study, the overall intra-operative and immediate postoperative complications were 2.5 and 10.8%, respectively, while late postoperative complications were 8.5% [5]. Persistent incontinence may occur in about 4% and impotence in 5% [6].

From a patient perspective the exposure to risk is of central importance; studies on shared decision-making programmes teach that patients who are provided with objective information relating to benefits and risks associated with different treatments to a greater degree choose therapies where the risk is minimised [7]. The risks associated with microwave treatment appear to be substantially smaller than risks associated with surgery [8, 9]. It would thus be an important complement to the treatment arsenal of BPH if microwave treatment could be used successfully in this patient category.

At our hospital, we have experience of microwave treatment since 1993 and have found the method easy to perform with only a few undesirable side-effects. The waiting time for surgery for all BPH patients at our hospital is presently so long that microwave thermotherapy has become an important supplementary modality. In addition the indication to use microwave treatment appears to be substantially smaller than risks associated with surgery [10, 11]. Reports of microwave treatment on patients with chronic retention are, however, rare in the literature [10, 11].

Due to the long waiting time for surgery at our hospital we have started to offer BPH patients with chronic retention and an indwelling catheter microwave treatment as an alternative to surgery. This report presents the first results with this treatment modality.

**Method**

24 unselected patients, 53–91 years old (mean age 73 years) with chronic urinary retention and an indwelling catheter underwent Prosta.Lund microwave feedback treatment between August 1997 and June 1999. Patients had had an indwelling catheter for 1–12 months prior to treatment. Patients were recruited in the order they registered to the clinic’s surgery waiting list (waiting time >6 months) and were offered microwave treatment within a few weeks as an alternative to surgery. All 24 patients accepted the offer. No patient selection was made, but all patients with BPH and chronic urine retention who wished to be treated were given the microwave treatment. The prostate length pre-operatively exceeded 45 mm in all cases, well above the minimum recommended length of 35 mm as specified by the microwave device manufacturer.

All patients were investigated pre-operatively with S-PSA, transrectal ultrasound for morphometry and volume determination (B&K Medical 3535), and fluid cystometry. Before treatment, at least 1 attempt to remove the indwelling catheter was made, in most cases 2 or more attempts. The patients were followed up at 3 and 12 months after treatment with morphometry and volume determinations, IPSS, bother score, Madsen score, urinary flow measurement (Dantec Urodyn 1000) and residual urine. Patients who were relieved of their indwelling catheter and had a bother score ≤ 2 and a residual urine ≤ 150 ml were considered responders to the treatment.

Treatments were carried out using the Prosta.Lund Feedback Treatment™ protocol (Prosta.Lund, Sweden). The Prosta.Lund device is an enhanced microwave system where the actual intraprostatic temperature is monitored and used to control the microwave power. The treatment catheter contains a microwave antenna which focuses mi-
after 3 months it had decreased to 53 ml (range 22–138 ml), and after 1 year it had decreased further to 46 ml (range 18–123 ml). Eight patients had an initial volume of 80 ml. The average reduction in prostate volume was 32% (26 ml) after 3 months and 42% (33 ml) after 1 year. According to the ProstaLund system’s cell kill estimation which is displayed online during treatment, the calculated destruction of tissue averaged 27 ml. In the non-responder group, the average prostate volume was 69 ml (range 47–102 ml) preoperatively and 38 ml (range 25–62 ml) at 3 months of follow-up, i.e. the volume reduction was in the same order as for the responder group. The residual urine in the non-responder group varied between 125 and 384 ml after treatment in 4 patients where it could occasionally be measured.

The average treatment time was 60 min (range 46–82 min) and the average microwave power during treatment was 59 W (range 30–77 W). The maximum prostate temperature recorded during treatment was on average 59.8°C (range 47.9–71.5°C). Posttreatment catheter time varied from 9 to 54 days for the responding group with an average of 26 days. Initially, we attempted to remove the catheter after 2 weeks, but this worked well only for about 1/3 of the patients. Later, we therefore decided to wait 4 weeks before attempting to remove the posttreatment catheter.

Patients tolerated treatment satisfactorily: 19 patients did not experience any discomfort, 3 patients experienced moderate discomfort, and 2 patients experienced significant discomfort mainly comprising urge sensation during treatment.

There were only a few posttreatment complications, and no patients required overnight stay or care in hospital: 1 patient experienced moderate haematuria for 2 weeks, and another patient received temporary catheter care for 2 weeks because of influenza 4 months after the treatment.

It is possible to distinguish 5 of 24 patients (20%) who were not relieved of their indwelling catheter. Patient 1 had protruding side lobes into the bladder that after treatment fell down and formed a valve in the bladder neck. Patient 2 was actually relieved of his indwelling catheter after the treatment, but he was accustomed to an open catheter at night-time. Now suffering from nocturia 2–3 times per night he requested the indwelling catheter back in order to be able to sleep without interruptions. Patients 3 and 4 had a median lobe that was unaffected by the treatment, and patient 5 had an undiagnosed bladder neck sclerosis. Four of these later underwent TURP with a satisfactory result.

**Discussion**

80% of the patients treated with the ProstaLund microwave system were relieved of their indwelling catheter, had low symptom and bother scores, adequate bladder emptying and acceptable urinary flow. There were no occurrences of serious complications such as bleeding requiring hospitalisation, sepsis or urinary incontinence. Surprisingly, the treatment appears to be insensitive to the prostate size. Outcome was equally satisfactory for patients with a severely enlarged prostate (>80 ml) where open prostate surgery would else have been the usually selected option. The satisfying outcome for this group of patients after a 1-hour-long out-patient procedure suggests that the ProstaLund Feedback Treatment can be a good alternative to surgery for patients with BPH and obstructive retention. The patient’s relief of being able to void spontaneously again is probably the primary factor to understand the high patient satisfaction rate of the treatment.

Treatment failed in 5 (20%) of 24 cases. The reasons for failure were identifiable in all cases and indicate that the method may be less suitable for patients with a large median lobe or severely protruding lobes in the bladder. The residual urine was considerably higher after treatment in the non-responder group suggesting that detrusor impairment is a contributing factor.

An interesting observation is that most patients experienced little or no discomfort during the treatment. An explanation can be that patients that carry an indwelling catheter for a long time become desensitised in the lower urinary tract. Postoperative catheter care and the weeks immediately following removal of the postoperative catheter were also endured without substantial discomfort or urge, despite the fact that the catheter period following microwave treatment was longer than usual, approximately 1 months compared to 1 or 2 weeks which is otherwise common for non-retention BPH patients that undergo microwave thermotherapy.

The underlying idea of thermotherapy is to create heat necrosis. The extent of the necrosis, or cell kill, is governed by two physical variables: the intraprostatic temperature and the duration of the heat exposure. Unfortunately, less relevant parameters that are secondary to the two fundamental ones are often seen in the literature to describe microwave thermotherapy, e.g. ‘low energy’ or ‘high energy’. In the presented material, we saw large variations in treatment duration and microwave power between patients which reflects large individual differences in prostatic blood flow which in turn governs the intraprostatic temperature. Patients with a low blood flow may very well be successfully treated with ‘low energy’ whereas patients with a high blood flow need to be treated with high microwave power to reach therapeutic intraprostatic temperatures. This fact stresses that microwave thermotherapy should be regarded as an individualised treatment – the microwave power should in each case be adjusted to the actual intraprostatic temperature.

**Conclusion**

The satisfying outcome of a 1-hour-long out-patient procedure for this patient category suggests that ProstaLund Feedback Treatment may be a good alternative to surgery for BPH patients with chronic retention and an indwelling catheter.

These positive preliminary findings will be followed by a randomised controlled multicentre study to further investigate the long-term efficacy, safety and health economy aspects of the ProstaLund Feedback Treatment compared to surgery for this patient category.
