Keywords: Vel blood group antigen, erythrocyte, integrative genomics.

The Vel antigen is present on red blood cells (RBCs) from all humans except rare Vel negative (Vel⁻) individuals who can form anti-Vel in response to transfusion or pregnancy. These antibodies may cause severe hemolytic reactions in blood recipients. We combined SNP profiling and transcriptional network modeling to link the Vel⁻ phenotype to *SMIM1*, located in a 97-kb haplotype block at chromosome 1p36. This gene encodes a previously undiscovered, evolutionarily conserved transmembrane protein expressed on RBCs. Remarkably, 35/35 Vel⁻ individuals were homozygous for a frameshifting 17-bp deletion in exon 3. Functional studies using antibodies raised against SMIM1 peptides confirmed a null phenotype in RBC membranes, and *SMIM1* overexpression induced Vel expression. Genotype screening estimated that ~1/17 Swedish blood donors are heterozygous deletion carriers, ~1/1,200 homozygous deletion knock-outs, and identified new Vel⁻ donors. Our results establish *SMIM1* as a novel erythroid gene, and Vel as a new blood group system.

Human RBCs carry functionally important proteins/glycoproteins on their surfaces. Allelic variation in the underlying genes determines the presence/absence of antigenic structures on these molecules, and, in turn, transfusion and transplant compatibility between individuals.

The Vel⁻ blood group phenotype was described in 1952 when Sussman *et al.* reported a patient who suffered an acute intravascular hemolytic episode following a blood transfusion¹. The patient made antibodies that reacted with all RBCs tested except her own. The newly defined antigen was named Vel. Subsequent reports of hemolytic reactions upon transfusion of Vel⁺ RBCs to Vel⁻ patients with anti-Vel, and of hemolytic disease in newborns of Vel⁻ mothers, have established Vel as a clinically important blood group antigen^{2,3}.

Since its description, Vel has eluded molecular identification. Population studies indicate a prevalence of Vel⁻ individuals at ~1/4,000 in Europe², but somewhat higher (~1/1,700) in northern Scandinavia^{2,4}. Family studies suggest that the Vel⁻ phenotype is inherited as an autosomal recessive trait, but no locus has been found^{4,5}. Similarly, efforts to identify a Vel carrier molecule have been inconclusive⁶. Hence, identification of Vel⁻ blood donors who can provide compatible blood to Vel⁻ patients with anti-Vel relies on typing with scarce polyclonal sera from immunized individuals – monoclonal reagents do not exist.

Because of the presumed inheritance pattern and higher prevalence in northern Scandinavia (a sparsely populated and historically isolated region), we hypothesized that the Vel⁻ phenotype could be caused by a homozygous founder mutation located in a chromosomal region with an identifiable SNP signature. We therefore SNP-profiled 20 Vel⁻ individuals (predominantly Swedish; **Supplementary Table 1**) using microarrays (2.44×10^6 SNPs).

We identified SNPs that segregated with the Vel⁻ phenotype by requiring a homozygous and identical SNP genotype in five Vel⁻ siblings from two families, and a different genotype in their Vel⁺ siblings (**Fig. 1a**). This filter identified 8,780 SNPs distributed across the genome. To test which of the segregating SNPs were enriched among Vel⁻ individuals, we compared minor allele frequencies among the 15 remaining/non-related Vel⁻ individuals to background frequencies calculated across 379 whole-genome-sequenced individuals of European ethnicity from the 1000 Genomes Project⁷. Strikingly, this revealed 25 highly enriched SNPs in a 97-kilobase haplotype block at chromosome 1p36, where all 20 Vel⁻ individuals showed the same SNP signature (**Fig. 1b** and **Supplementary Table 2**).

The region at 1p36 contains 5 annotated genes (**Fig. 1c** and **Supplementary Table 3**). To prioritize, we inferred a genome-wide gene-regulatory network from 2,096 pre-existing gene expression profiles⁸ of human bone marrow samples. Here, *SMIMI* (Small integral

membrane protein 1) stood out as its network neighborhood was dominated by known blood group genes and erythroid genes (**Fig. 2**). Furthermore, SMIM1 has been predicted as a transmembrane protein (www.uniprot.org), contains binding sites for erythroid transcription factors like GATA-1⁹ (**Supplementary Table 4**), is highly expressed in erythroleukemia cell lines (**Supplementary Fig. 1**), and is up-regulated in human CD34+ hematopoietic progenitors cultured towards RBCs (**Supplementary Fig. 2**). These results implicated SMIM1 as an erythroid transmembrane protein, an ideal candidate gene.

According to the current human genome annotation, *SMIM1* has four exons and encodes a 78-amino-acid protein (calculated weight ~8.7 kDa). Computational sequence analysis predicted a type 1 transmembrane protein with an extracellular portion of ~50-amino-acid portion containing potential O-glycosylation sites, a transmembrane domain containing a GxxxG motif, a short intracellular tail, but no other functional motifs (**Fig. 3a, b** and **Supplementary Table 5**). Interestingly, protein sequence alignment found no homologs in humans, but 56 orthologs in 45 other species, from primates to sea squirt. Cross-species genome sequence alignment uncovered a conserved GATA motif in primates and rodents, suggesting that *SMIM1* is expressed in the erythroid lineage in higher mammals (**Fig. 3c** and **Supplementary Fig. 3**). Consistent with the informatics, we detected *SMIM1* transcripts in total blood RNA by qPCR, both from Vel+ and Vel- individuals (not shown).

Sequencing of *SMIM1* revealed homozygosity for a 17-bp deletion in the coding region of exon 3 in all 20 Vel- individuals whereas Vel+ controls showed consensus sequence (**Supplementary Fig. 4**). Because the deletion and its surrounding SNP signature is identical in all cases, it is a likely founder mutation. To ascertain that the deletion is truly associated with the Vel- phenotype, we collected DNA from 15 additional Vel- individuals (predominantly European; **Supplementary Table 1**). Remarkably, all cases in this independent validation cohort were homozygous for the same 17-bp deletion. Directed

genotyping (**Fig. 3d**) of 520 Swedish blood donors revealed 30 heterozygous deletion carriers but no homozygotes. These results establish that the 17-bp deletion in *SMIM1* is associated with the Vel⁻ phenotype, and that it is not restricted to the Swedish population.

Assuming Hardy-Weinberg equilibrium, an estimated heterozygote frequency of 30/520 ($\sim 1/17$) predicts $\sim 1/1,200$ homozygotes. Importantly, this figure does not differ significantly from the reported prevalence of $\sim 1/1,700$ Vel⁻ individuals⁴ (binomial test; $P=0.26$). Further, while the deletion is not called in 1000 Genomes, the NHLBI Exome Sequencing Project (ESP) lists allele frequencies of 57/5,763 in European Americans and 6/3,198 in African Americans, yielding heterozygote frequencies of $\sim 1/50$ and $\sim 1/267$. While indel detection by high-throughput sequencing has algorithm-dependent sensitivity, a lower frequency in Europeans than in Swedes agrees with lower prevalences of Vel⁻ individuals². ESP lists the 17-bp deletion as the most common non-consensus coding variant in *SMIM1* (**Supplementary Table 6**), although existence of alternative null alleles cannot be excluded.

The 17-bp deletion introduces a frameshift 5' of the encoded transmembrane domain. With Vel⁺ blood, 5'/3'-RACE showed that the wildtype transcript contains the complete coding sequence, and an unannotated non-coding exon 1 (**Supplementary Fig. 5**). With Vel⁻ blood, no capped and polyadenylated mRNA was captured despite repeated attempts. With a known heterozygote, RACE yielded only the wildtype sequence. These data suggest that the mutant transcripts could be subject to degradation by mRNA surveillance mechanisms, as expected from the frameshift^{10,11}.

To explore a null/knock-out phenotype, we synthesized peptides corresponding to the predicted extracellular domain of SMIM1, and raised rabbit polyclonal antibodies. While these sera did not hemagglutinate RBCs, Western blotting under reducing conditions showed bands at ~ 9 – 10 and ~ 20 kDa with RBC membranes from Vel⁺ blood, and Glycophorin A (GPA) positive bone marrow cells. Human anti-Vel showed similar reactivity with reduced

Vel+ membranes. Neither band was present in Vel- membranes or Vel+ non-erythroid bone marrow cells (**Fig. 4a–c**). Hence, SMIM1 is present on Vel+, but not Vel-, erythroid cells. Moreover, analysis of microarray profiles of human tissues showed high *SMIM1* expression in bone marrow, and lower levels in non-hematopoietic tissues (**Supplementary Fig. 6**).

The detection of two bands with anti-SMIM1 (at $\sim 1\times$ and $\sim 2\times$ the calculated SMIM1 weight) suggests that the protein forms reduction-resistant homodimers. This is consistent with the presence of the GxxxG motif which mediates transmembrane dimerization via helix-helix association^{12,13}, as shown for GPA¹⁴. Additionally, Western blotting under non-reducing conditions showed broad reactivity, suggesting that SMIM1 forms disulfide-dependent complexes with itself or other, as yet unidentified, proteins (**Fig. 4c**). Further biochemical studies confirmed that SMIM1 orients its N-terminal extracellularly, and indicated that O-glycans may not be involved in the Vel epitope (**Fig. 5**).

To verify that Vel depends on *SMIM1*, we over-expressed its cDNA in the erythroleukemic cell line K562. In multiple experiments, we observed increased cell surface expression of Vel in *SMIM1*-transfected, but not mock- or mutant-transfected, cells by flow cytometry with human anti-Vel, accompanied by increased protein expression as shown by anti-SMIM1 (**Fig. 4d,e**). This confirms *SMIM1* as the gene underlying Vel antigen expression.

Finally, we compared Vel expression on RBCs from individuals heterozygous or negative for the deletion. Consistent with the transfections, this revealed a strong correlation between Vel expression and *SMIM1* deletion zygosity, most likely as a gene dose effect (**Fig. 4f,g**).

The Vel antigen has been elusive for 60 years. We show that allelic variation in *SMIM1* defines the Vel blood group system, and link the Vel- phenotype to a founder null allele. It is remarkable that the genetic basis of the Vel- phenotype is identical in 35 individuals, as this contrasts with the heterogenous backgrounds of other recently resolved blood groups^{15,16,17}.

Importantly, this discovery enables identification of rare Vel⁻ blood donors by genotyping¹⁸. Screening for the 17-bp deletion was implemented at the Regional Blood Center in Lund, Sweden. To date, two new homozygotes were found, and confirmed serologically as Vel⁻. This demonstrates how our findings facilitate procurement of compatible blood for Vel-immunized patients, who risk delayed transfusion support and worse outcomes¹⁹.

The identification of *SMIM1* as an erythroid gene – encoding a novel transmembrane protein – raises intriguing questions. Firstly, the protein's functional and molecular context awaits further exploration. Strikingly, there are similarities with glycophorins, especially GPA, a short, type 1, O-glycosylated transmembrane protein that forms reduction-resistant dimers via its GxxxG motif¹⁴. Secondly, conservation across species indicates an important function, particularly in higher-mammal erythropoiesis. This raises the question whether Vel⁻ individuals, who are in fact human knock-outs, exhibit as yet unrecognized hematologic features. Thirdly, it is conceivable that pathogens utilize SMIM1 as an invasion receptor, similarly to how malarial parasites exploit other blood-group carriers^{20,21,22}. In fact, given our data in **Fig. 5** and the similarities with GPA, it is possible that SMIM1 represents the long-sought α -chymotrypsin-sensitive *Plasmodium falciparum* receptor²³. Future studies will uncover the roles of SMIM1 in hematopoiesis and human disease.

METHODS

Methods and any associated references are available in the online version of the paper.

Accession codes: The genomic *SMIMI* mutant sequence containing the 17-bp deletion, and the new erythroid cDNA wildtype sequence determined by RACE experiments, have been deposited in Genbank under accession numbers KC152643 and KC152644, respectively.

ACKNOWLEDGEMENTS

The study was supported by research grants from the Swedish Foundation for Strategic Research (no. ICA08-0057 to B.N.), the Swedish Research Council (no. 14251 to M.L.O.), governmental ALF grants to the University and Regional Laboratories (Labmedicin Skåne; to J.R.S., M.J., B.N., M.L.O.), the Medical Faculty at Lund University (B.N., M.L.O.), the Skåne County Council's Research and Development foundation, Sweden (M.L.O.), Marianne and Marcus Wallenberg's foundation (no. 2010.0112 to B.N.), Harald Jeansson's Foundation (B.N.), Swedish Society of Medicine (B.N.), the National Blood Foundation (J.R.S.), and Glashofs Legat (no. 302499 to M.K.C.). We thank Joyce Poole, Jan Hamilton, Hein Hustinx, and the SCARF exchange scheme for kindly providing samples for this study. We thank Jörgen Adolfsson, Linnea Järvstråt, and Annika Hult for technical assistance. We are indebted to the individuals and their families who participated in this project.

AUTHOR CONTRIBUTIONS

J.R.S., B.N., M.L.O. conceived, designed, and coordinated the study. M.J. and B.N. performed genomic, bioinformatic, and computational analyses. J.R.S. performed DNA

sequence analysis and protein chemistry. B.T. designed, and M.K.C. performed RACE, qPCR and over-expression experiments. J.R.S. and M.K.C. performed FACS analysis. B.N.S. contributed background knowledge, performed serological screening, and enrolled blood donors. B.Å. contributed to experimental design and the early conception of the project. J.R.S., M.J., B.N. and M.L.O. discovered the 17-bp deletion in *SMIM1* and wrote the paper. All authors contributed to the final manuscript.

COMPETING FINANCIAL INTERESTS

The authors declare no competing financial interests. A patent application covering Vel typing using genetic information from *SMIM1* has been filed (J.R.S., M.J., B.N., and M.L.O.).

FIGURE LEGENDS

Figure 1: Genome-wide SNP profiling maps the locus of the Vel– phenotype to chromosome 1p36. (a) Because of a reported enrichment of Vel– individuals in northern Sweden⁴ and anticipated autosomal recessive inheritance, we hypothesized that the Vel– phenotype could be caused by a founder mutation. We analyzed 15 non-familial (predominantly Swedish; **Supplementary Table 1**) and 5 familial Vel– individuals (A1, A2, B6, B7 and B8 in pedigrees; families from Sweden) and their siblings (A3 and B9) on Illumina Human-Omni 2.5M BeadChip microarrays (2.44×10^6 SNPs). **(b)** Based on the familial genotypes, we identified 8,780 SNPs that segregated homozygously with the Vel– phenotype. Each of these SNPs was tested for over-representation among Vel– individuals by comparing their allele frequencies across the 15 non-familial cases with background frequencies calculated from whole-genome-sequence data for 379 individuals of European ethnicity from the 1000 Genomes Project⁷. This identified 25 strongly significant SNPs at 1p36. The *x*-axis indicates SNP locations, the *y*-axis $-\log_{10} P$ values for Fisher’s exact test (red bar indicates the $P < 10^{-8}$ threshold). **(c)** All 25 significant SNPs were located inside a 97-kb haplotype block that contains five genes (*CCDC27*, *SMIM1*, *LRRC47*, *CEP104*, and *DFFB*; see **Supplementary Table 3**), and is flanked by recombination hotspots in *CCDC27* and *DFFB*. Blue line indicates local recombination rates estimated from the 1000 Genomes data. Red color reflects association with the most significant SNP rs12729572. All Vel– individuals showed the same SNP signature in the identified region (**Supplementary Table 2**).

Figure 2: Identification of SMIM1 as a previously uncharacterized transmembrane protein expressed in erythroid cells. Because most blood group genes are expressed in erythroid cells, we prioritized the genes in the region at 1p36 by computing a genome-wide gene-regulatory network for human hematopoiesis from 2,096 gene expression profiles of bone marrow samples⁸. Using a new computational tool, Ultramet²⁴, we created a Gaussian Graphical Model which is a sparse graph where nodes represent genes (n=20,958), and vertices correlations in expression between genes that cannot be explained by confounding co-correlation with other observed genes. The network neighborhood of each gene was defined as the set of first- and second-degree neighbor genes in the graph. Strikingly, the neighborhood of *SMIM1* contained 17 of 35 known blood group genes (red; χ^2 test for enrichment, $P < 1.0 \times 10^{-10}$), and was dominated by erythroid genes, including the erythropoietin receptor (*EPOR*), heme synthesis genes (*UROD*, *HMBS*, *BLVRB*, *ALAD*, *ALAS1*, *CPOX*, *FECH*), hemoglobin genes (*HBB*, *HBM*, *HBQ1*), erythroid transcription factors (*GATA1*, *KLF1*, *GFI1B*, *TAL1*, *SOX6*), and erythroid membrane proteins (numerous). By contrast, the neighborhoods of the other four candidate genes contained fewer genes and no erythroid genes or blood group genes (not shown). This finding, along with protein sequence analysis (UniProt accession no. B2RUZ4 and **Fig. 3b**) and additional gene expression microarray data (**Supplementary Figs. 1 and 2**), predicted *SMIM1* as a previously undiscovered transmembrane protein expressed in erythroid cells.

Figure 3: Founder mutation in SMIM1 explains a null/knock-out phenotype in Vel+ RBC membranes. (a) In the current (GRCh37) genome annotation, *SMIM1* has four exons (reference sequence NM_001163724.1). All 20 Vel⁻ individuals in the discovery cohort were homozygous for a 17-bp deletion (red) in exon 3, as were an additional 15 Vel⁻ individuals. **(b)** *SMIM1* encodes a protein of 78 amino acids, ~50 of which constitute the extracellular domain. Potential O-glycosylation (S/T residues) and oligomerization (C residues and GxxxG transmembrane motif) sites are indicated. The 17-bp deletion introduces a frameshift from serine 22. **(c)** Cross-species sequence alignment found no protein homologs in humans, but 56 orthologs in 45 other species (11 shown; see also **Supplementary Fig. 4**). The GATA motif in intron 2 (**Supplementary Table 4**) is conserved in primates and rodents, implicating *SMIM1* in higher-mammal erythropoiesis. Conserved amino acids are color coded according to their properties (green: hydrophobic nonpolar; yellow: polar uncharged; orange: acidic; blue: basic). Bars indicate degree of conservation. **(d)** To exclude a common variant, we designed a PCR assay enabling discrimination of consensus/wildtype (w) and deletion/mutant (m) alleles. Genotyping of 520 random Swedish blood donors revealed 30 heterozygous deletion carriers and no homozygotes, showing that the homozygous 17-bp deletion is linked to the Vel⁻ phenotype. Analysis of whole-exome sequence data from several thousand individuals revealed that the 17-bp deletion is the most common coding non-consensus variant in *SMIM1* (**Supplementary Table 6**).

Figure 4: Confirmation of *SMIM1* as the gene underlying Vel expression. **(a)** Western blotting of reduced solubilized RBC membranes with rabbit polyclonal anti-SMIM1. Two bands at ~9-10 and ~20 kDa seen in Vel+ samples. Weaker bands were observed in the deletion-heterozygous sample (Vel+^w). Vel- membranes were non-reactive. **(b)** Western blotting of sorted bone marrow cells with rabbit polyclonal anti-SMIM1, compared with Vel+ and Vel- RBCs. Only CD235a (GPA) positive cells were reactive, indicating that SMIM1 is restricted to the erythroid lineage. Anti-GAPDH loading controls shown in the bottom panels. **(c)** Western blotting with three human anti-Vel sera (designated 1–3) with nonreduced Vel+ and Vel- membranes as indicated, and reduced Vel+ membranes (right-most lane). Thus, anti-Vel and anti-SMIM1 identify similar-sized bands in reduced membranes. Anti-SMIM1 reacts broadly with non-reduced membranes (not shown). **(d)** *SMIM1* over-expression in K562 cells. Cell surface expression of Vel, measured by flow-cytometry with human anti-Vel (ratio of PE positivity/GFP expression; normalized against mock-transfected cells). Mock=pEF1αIRES-ZsGreen1 empty/control vector; SMIM1-mut=pEF1α vector with *SMIM1* containing 17-bp deletion; SMIM1-wt=pEF1α vector with wildtype *SMIM1*). **(e)** Western blotting with anti-SMIM1 shows parallel increase in SMIM1-protein expression. **(f)** Vel expression correlates strongly with *SMIM1* deletion zygosity. To semi-quantify Vel, we used mean fluorescence intensity given as a ratio of human anti-Vel reactivity vs. AB serum in m/m (n=1), w/m (n=16) and w/w (n=21) individuals. Asterisks indicate $P<0.001$ (unpaired Student's *t*-test); the error bars reflect standard error of the mean (SEM). **(g)** The representative histogram shows the differences in antigen expression.

Figure 5: Enzymatic characterization of the extracellular domain of SMIM1. To show that SMIM1 was located on the extracellular surface, anti-SMIM1 reactivity following protease- or glycosidase-treatment of intact RBCs was investigated. Reduced staining of protease-treated RBCs at **(a)** 10 seconds exposure, **(b)** 1 minute exposure, is consistent with overall peptide degradation of the extracellular proteins. This was dose-dependent with both papain (P) and trypsin (T) since 1/100 dilutions of both enzymes (P 1:100 and C 1:100) did not affect reactivity; however, SMIM1 demonstrated an increased sensitivity to α -chymotrypsin (C and C 1:100). **(c)** Reprobing with anti-GPA/B (clone E3, Sigma; 1:10,000) shows sensitivity to papain and α -chymotrypsin, (although a relative resistance to trypsin) and also, the expected shift in molecular weight following treatment with O-glycosidase whereas no effect on SMIM1 reactivity is observed with O-glycosidase treatment. Additionally, we performed hemagglutination experiments with human anti-Vel and RBCs treated with neuraminidase, O-glycosidase or combined neuraminidase + O-glycosidase to assess if Vel reactivity was altered by removing O-glycans. In line with *in silico* predictions (**Supplementary Fig. 7**), and consistent with the Western blot with anti-SMIM1, there was no change in hemagglutination titer/score (not shown). While this does not exclude the presence of minor O-glycan components on SMIM1, it suggests that O-glycans do not play a major role in Vel antigenicity. **(d)** Commassie staining of treated membranes. **(e)** Available cleavage sites in SMIM1 for trypsin (red) and α -chymotrypsin (blue) showing the relative abundance of α -chymotrypsin sites that might explain the unexpected sensitivity. Predicted transmembrane sequence is underlined.

ONLINE METHODS

Samples

Subject to ethics approval and informed consent, anonymized bone marrow samples from healthy volunteers, buffy coat waste material from routine blood donations, and blood samples were obtained from various sources (**Supplementary Table 1**). DNA panels for screening were anonymized collections of 520 unselected Swedish blood donors. No donors were approached solely for the purpose of this study.

Nucleic acid preparation

Genomic DNA was prepared using a modified salting-out procedure²⁵ and diluted to 100 ng/ μ L; or the QIAamp DNA Blood Mini Kit (Qiagen) and used undiluted. Total RNA was extracted from whole blood or cell lines using Trizol® LS (Life Technologies Europe).

SNP genotyping and SNP data analysis

A total of 20 Vel- and 8 Vel+ individuals were genotyped on HumanOmni 2.5M BeadChip microarrays probing 2,443,179 SNPs (Illumina; analysis performed at the SCIBLU genomics facility at Lund University). Genotypes were called in Illumina GenomeStudio (call rate >99.5% for all samples; four samples genotyped twice with >99.3% concordance). To estimate background allele frequencies, we used whole-genome sequence data from 379 individuals of European ethnicity from the 1000 Genomes Project⁷ (because a high-resolution Swedish SNP data set was unavailable). Allele frequencies were compared by Fisher's exact test with $P < 10^{-8}$ as significance threshold. The linkage disequilibrium boundaries of the detected haplotype block were estimated from the unfiltered genotype calls (**Supplementary Table 2**). These boundaries coincided with regions of high recombination rate in the 1000

Genomes Project CEU population. While SNP data for the identified region at 1p36 is given in **Supplementary Table 2**, the complete SNP data are not publicly available to protect the identity of the study participants, as individuals can be identified from SNP profiles.

Network modeling

To infer gene-regulatory networks, we used a new high-performance tool (Ultramet²⁴), which enables computation of Graphical Gaussian Models at a genome scale. As input data, we used 2,096 Affymetrix U133A Plus 2 gene expression profiles of human bone marrow from different conditions⁸ (NCBI Gene Expression Omnibus; accession no. GSE13159). Ultramet's parameter λ controls the sparsity of the network. In **Fig. 2**, $\lambda=0.75$. Other reasonable values yielded agreeing results.

Bioinformatic characterization of *SMIM1*

To predict the location of the transmembrane domain, we used nine different computational tools (**Supplementary Table 5**). To find homologs, we searched the Refseq non-redundant, Ensembl (release 68) and UniProtKB data bases, and retrieved alignment data from UCSC Genome Browser (table knownGene.exonAA). BLASTP was performed using an *E*-value cut-off of 1. To search for conserved protein domains, we used NCBI Conserved Domains. To perform cross-species genome sequence alignment, we used UCSC Genome Browser.

ChIP-seq data from ENCODE⁹ obtained via UCSC Genome Browser were examined for transcription factor binding sites in *SMIM1* (**Supplementary Table 4**). Whole-exome sequence data from the Exome Sequencing Project were obtained from NHLBI Exome Variant Server (**Supplementary Table 6**).

Genetic analysis of *SMIM1*

Genomic DNA from 35 Vel[−] and 10 Vel⁺ samples were amplified with primers 388588int2f and 388588ex4r which flank the *SMIM1* open reading frame (**Supplementary Table 7**). Amplified products were sequenced using the BigDye Terminator v3.1 Cycle Sequencing Kit (Applied Biosystems, Life Technologies) on an ABI 3500 Dx Genetic Analyzer. Analyses were performed using CodonCode Aligner.

We developed genotyping methods to allow discrimination of consensus/wildtype and deletion/mutant *SMIM1* alleles (**Supplementary Fig. 8**). To screen blood donors, we used exon 3-specific PCR based on primers LOCex3f_screen and LOCex3r_screen (**Supplementary Table 7**). Allele-specific PCR products of 178 bp (wildtype) or 161 bp (mutant) were discriminated by agarose-gel electrophoresis (**Fig. 3c**).

Transcript analysis

Total RNA from whole blood or cell lines were converted to cDNA using the High Capacity RNA-to-cDNA Kit (Applied Biosystems). mRNA was amplified with the Expand High Fidelity PCR system (Roche Diagnostics) using primers 388588cDNAf and 388588cDNAr, and the products were sequenced.

A TaqMan® Gene Expression Assay (Hs01369635_g1, Applied Biosystems, binding to the exon 3–4 boundary) was used in real-time qPCR for the detection of *SMIM1* transcripts. Transcript quantities were normalized to human β -actin RNA (Invitrogen assay 4333762F). All samples were run in triplicate, and calibrated against the sample with the lowest C_T value. Triplicates with ≥ 2 C_T values <40 were considered positive.

Messenger RNA was isolated from total blood RNA by an mRNA Isolation Kit (Roche Diagnostics). RACE was performed with the FirstChoice RLM-RACE kit (Ambion). In 5'-RACE experiments, cDNA was synthesized with random or oligo-dT primers. Gene-specific

primers Vel 332R, Vel 355R and Vel 376R were used for nested PCR amplification together with the 5'-RACE forward primers provided in the kit. For the 3'-RACE, cDNA was obtained with the provided adapter, and nested PCR was performed with primers Vel 59F, Vel 176F and Vel 280F, together with the 3'-RACE reverse primers. PCR products were analyzed by gel electrophoresis, eluted with QIAquick Gel Extraction Kit (Qiagen) and sequenced as described above. Primer sequences are shown in **Supplementary Table 7**.

Generation of rabbit antibodies

Four overlapping peptides were designed from the predicted extracellular domain of SMIM1 (**Supplementary Table 8**). Peptides 1 and 3 were selected to produce rabbit polyclonal antibodies to the predicted SMIM1 protein (Innovagen AB). Partial inhibition of human anti-Vel reactivity with a pool of the peptides was demonstrated (**Supplementary Fig. 9**). While the antibodies were highly specific by Western blotting (**Fig. 4**), they did not hemagglutinate RBCs, nor were they successful in immunoprecipitation protocols. This suggests that they recognized a linear epitope but not the conformational Vel antigen on intact RBCs.

SDS-PAGE and Western Blot analysis

RBC membranes were prepared as described previously²⁶, and solubilized with 1% Nonidet P-40. The solubilize was mixed with equal volumes of Laemmli sample buffer with or without the addition of 5% mercaptoethanol depending on the conditions required and run on NuPAGE® 12% or 4–12% Bis-Tris gels (Novex, Life Technologies). The gel was either stained with SimplyBlue™ SafeStain (Life Technologies), or the proteins transferred onto polyvinylidene difluoride (PVDF) membranes. Following blocking in 5% non-fat milk/phosphate-buffered saline (PBS), the membranes were incubated with primary antibody (anti-SMIM1, 1:20,000; affinity-purified human anti-Vel) for 2 hours at room temperature (RT). Following washing in PBS/Tween (PBST), incubation followed for 1 hour at RT with

horseradish peroxidase (HRP)-labelled goat anti-IgG (rabbit, Agrisera; human BioRad) diluted 1:10,000 in PBS-T. The membranes were developed with ECL reagent (Life Technologies), exposed to film for an appropriate time as determined by an initial 60 second exposure, and developed. The membranes were reprobed with a murine anti-GAPDH (clone 6C5, Millipore), diluted 1:5,000, washed and incubated with HRP-labelled goat anti-mouse IgG (BioRad) diluted 1:10,000 in PBS-T; and visualized as above (**Fig. 4**).

Over-expression experiments

The full coding sequence of *SMIM1* was amplified from cDNA using primers VelF and VelR2 (**Supplementary Table 7**), and inserted into a green fluorescent protein-positive plasmid pEF1 α -IRES2-ZsGreen1 vector (Clontech) following *EcoRI/BamHI* digestion. NEB5- α competent *E. coli* (New England Biolabs) were transformed, and positive colonies were PCR-amplified and sequenced to confirm the insert. pEF1 α vectors containing the wildtype sequence (pEF1 α -SMIM1wt), mutant sequence (pEF1 α -SMIM1mut) or empty vector (pEF1 α -mock) were selected and prepared using Plasmid Midi Kit (Qiagen).

K562 cells were cultured in RPMI 1640 medium (Gibco, Life Technologies) supplemented with 10% fetal bovine serum (Gibco) at 37°C and 5% CO₂. Upon transfection, 5 \times 10⁶ K562 cells were mixed with 10 μ g pEF1 α -vectors, electroporated using the Gene Pulser II electroporation system (BioRad) and incubated for 48 hours in 6-well culture plates (Nunc).

Flow cytometry

Flow cytometry was performed on RBCs, cell lines and transfected K562 cells. A suspension of \sim 0.5 \times 10⁶ RBCs or 10⁶ K562 cells in PBS containing 1% bovine serum albumin (PBS/BSA) were tested with human group AB anti-Vel (selected after screening of several anti-Vel reagents) or normal AB serum (isotype control). Either FITC-conjugated F(ab')₂

Fragment Rabbit Anti-Human IgG (Dako, Electra-Box Diagnostica AB) (RBCs) or R-Phycoerythrin(PE)-conjugated AffiniPure F(ab')₂ Fragment Goat Anti-Human IgG (Jackson ImmunoResearch Europe Ltd) (cell lines and transfected cells) were used as secondary antibodies. Analysis (10,000 events/RBCs; 50,000 events/transfected cells) was performed with the FACSCalibur cell cytometer (Becton Dickinson) using CellQuest™ 3.3 software (Becton Dickinson). PE-conjugated anti-CD33 (Dako, Life Technologies) and 7-AAD (BD Pharmingen) were used as positive compensation controls in tricolor FACS analysis (transfected cells). Viable cells were gated for double-positive signal in the GFP- and PE-channels and assumed to be Vel+ (transfected K562 cells).

Cell populations were sorted from human bone marrow with the following antibodies: CD3-V500, clone UCHT1; CD16-APC-Cy7, clone V NK89; CD19-AlexaFluor 488, clone HIB19; CD34-Fitc, clone 581; CD56-V450, clone B159 (all from Becton Dickinson); CD235ab-APC, Clone HIR2 (Biolegend).

Serologic analysis

Standard agglutination techniques were used for identification of anti-Vel, RBC phenotyping and hemagglutination/inhibition tests²⁷. Anti-Vel was affinity-purified by adsorption onto and elution from Vel+ RBCs. Eluates were prepared using the Elu-Kit II kit (Immucor).

Enzyme treatment

RBCs were treated with enzymes (Sigma-Aldrich), including papain (0.1%/0.001%), trypsin (1%/0.01%), α -chymotrypsin (0.5%/0.005%), neuraminidase + O-glycosidase, and O-glycosidase only. For protease treatment, 100 μ L washed packed RBCs were incubated with 100 μ L enzyme for one hour at 37°C. Glycosidase treatment was performed by (a) incubating 100 μ L washed packed RBCs with 0.05 U neuraminidase diluted in 100 μ L PBS for one hour at 37°C, then adding 0.02 U O-glycosidase diluted in 100 μ L PBS for a further hour's

incubation; and (b) washed packed RBCs were incubated only with O-glycosidase. RBC membranes were prepared directly following enzyme treatment.

Statistical analysis

Statistical tests were performed in R (<http://www.r-project.org/>) or Excel (Microsoft). For single-hypothesis tests, *P*-values <0.05 were considered significant.

Establishing Vel as a blood group system

The information presented in this paper fulfills the formal requirements to establish Vel as a novel human blood group system. Based on the available data, the current chair (J.R.S.) and two members (current secretary Christine Lomas-Francis, M.Sc, FIBMS, and former chair Dr. Geoff Daniels) of the International Society of Blood Transfusion (ISBT) Working Party for Red Cell Immunogenetics and Blood Group Terminology have assigned a provisional blood group system name and number, “Vel, system no. 34”, and promoted Vel from a genetically unresolved blood group antigen (ISBT no. 212001) to the new system defined by the *SMIMI* locus (as antigen no. 034001).

Supplementary Table 2: Unfiltered genotype calls for all subjects in the chromosome 1 candidate region

Unfiltered genotype calls for all subjects (n=28) in the chromosome 1 candidate region. Coordinates are GRCh37. Genotypes of Vel⁻ subjects (n=20) are printed in bold font. SNPs where all Vel⁻ subjects have identical genotype are highlighted in yellow. Genes in the region are shown in the right margin.

LOC100133612

Supplementary Table 3: Genes in the identified region at 1p36

This table lists the five genes in the identified region at 1p36, along with their predicted number of amino acids, predicted molecular weights, and annotated functions as based on the information in the Entrez Gene database.

Symbol	Name	AAs* (kDa)	Functional annotation
<i>CCDC27</i>	Coiled-coil domain-containing protein 27	656 (75.4)	no annotation
<i>SMIM1</i>	Small integral membrane protein 1	78 (8.7)	single-pass transmembrane protein
<i>LRRC47</i>	Leucine-rich repeat-containing protein 47	583 (63.4)	RNA-binding, phenylalanine-tRNA ligase
<i>CEP104</i>	Centrosomal protein 104kDa	925 (104.4)	centriole, cytoskeleton
<i>DFFB</i>	DNA fragmentation factor, 40kDa, beta polypeptide	338 (39.1)	nucleus, apoptosis factor

*) predicted/annotated number of amino acids.

Supplementary Table 4: ChIP-seq peaks

The table lists all transcription sites detected by ChIP-seq (chromatin immunoprecipitation followed by massively parallel sequencing) in *SMIM1*, including 500 bp upstream and downstream of the gene, in the ENCODE project¹ (data obtained through UCSC Genome Browser).

Antibody target	Antibody	Peak span(s)
BCL3	BCL3	Intron 2 3' region
BHLHE40	BHLHE40	Exon 4 – 3' region

Supplementary Table 6: *SMIM1* variants in larger populations

This table lists all variants in *SMIM1* (formerly *LOC388588*) detected by whole-exome sequencing in the NHLBI Exome Sequencing Project (ESP) in European Americans (EA) and African Americans (AA). As shown, the 17-bp deletion is the most common non-consensus variant detected in EA, and the only variant whose allele frequency predicts a homozygote frequency that is on par with the prevalence of Vel⁺ individuals among individuals of European ethnicity. The most common variant among AA is a noncoding GC/G indel of unknown significance in the three-prime untranslated region. The remaining variants occur at extremely low frequencies.

Chr 1 pos	Alleles (minor/major)	EA allele counts	AA allele counts	PolyPhen Prediction	Comment
3691980	A/G	1/3181	0/1384	benign	Asn15Asp
3691997	A/AGTCAGCCTAGGGGCTGT	57/5763	6/3198	unknown	frameshift
3692333	C/T	1/3181	0/1384	unknown	intronic
3692435	A/ATCT	7/5061	0/2834	unknown	in-frame deletion
3692460	G/GC	1/5021	0/2812	unknown	frameshift

Supplementary Table 8: Peptides

This table lists four peptides designed from the predicted extracellular domain of SMIM1. Peptides 1 and 3 were selected to produce rabbit polyclonal antibodies to the predicted SMIM1 protein.

Name	Sequence
Peptide 1	MQPQESHVHYSRWED
Peptide 2	SRWEDGSRDGVSLGA
Peptide 3	GVSLGAVSSTEEASR
Peptide 4	EASRCRRISQRLCTG

Supplementary Figure 1: *SMIM1* transcript expression in cell lines

Expression of the *SMIM1* (formerly *LOC388588*) transcript, as measured by microarray across 974 cell lines in the Broad-Novartis Cancer Cell Line Encyclopedia (<http://www.broadinstitute/ccle/home>; version June 2012). As shown, *SMIM1* is highest expressed in cell lines derived from examples of Chronic Myeloid Leukemia (CML) or Acute Myeloid Leukemia (AML). The highest-expressing lines were HEL and JK-1, which have erythroid differentiation. The erythroleukemic cell line K562 used for transfection experiments expresses *SMIM1* at moderate levels (not shown).

Supplementary Figure 2: *SMIM1* expression in CD34+ hematopoietic progenitors cultured towards RBCs

This figure shows the expression of *SMIM1* as measured on Affymetrix microarrays. In this experiment, which was performed by Keller and coworkers¹, adult differentiating CD34+ hematopoietic progenitor cells were cultured towards RBCs, and gene expression-profiled at various time points up to eleven days of growth in serum-free medium containing erythropoietin, interleukin 3 and stem cell factor. The purpose of the experiment was to identify transcriptional regulators involved in erythroid development at a global level. We specifically extracted the *SMIM1*-targeting probe from this data set (Affymetrix probe set identifier 230840_at). As shown, *SMIM1* is induced around day 9. The original data set is available in NCBI Gene Expression Omnibus, accession no. GSE4655. The experiment was performed in triplicate. Error bars indicate min to max. In accordance with the above, our data based on cDNA amplification of RNA derived from bone marrow cells cultured towards erythropoiesis² confirms the presence of *SMIM1* transcripts on days 3 and 9 in culture, with a tendency towards increased levels on day 9 (Data not shown).

Supplementary Figure 3: Cross-species alignment

Multiple sequence alignment for all homologous proteins found with BLASTP in the Refseq non-redundant and UniProtKB databases, in alignment data from UCSC Genome Browser (table knownGene.exonAA) or in Ensembl (release 68). An *E*-value of 1 was used as cut-off in BLASTP searches. No human homologs were found (human SMIM1 is included for reference), but a total of 56 protein orthologs with significant sequence similarity in 45 additional species.

Rows are labelled with species name and source (description below). Multiple sequence alignment was performed using MUSCLE v. 3.8.31 with default parameters. Bars at top indicate degree of conservation. Conserved amino acids are color coded according to their hydrophobic properties. The black bar at the bottom indicate the position of the predicted transmembrane domain in human, as determined by the computational tools listed in **Supplementary Table 5**.

Supplementary Figure 4: Sequence data

This figure shows the DNA sequencing results for **(a)** a homozygous Vel+ individual; **(b)** a Vel− individual; **(c)**, **(d)** a Vel+ heterozygous individual. Panel **(c)** shows sequencing results initiated with a primer in intron 2; **(d)** shows sequencing initiated by a primer in intron 3. The direction of the sequencing primer is indicated by the black arrow. The nucleotides deleted in the Vel− individual are shown by the black box. The sequence 5′ of the deletion is boxed in blue. The sequence 3′ of the deletion is boxed in red. In (c) and (d), the wildtype sequence is shown on top of the mutant sequence. The Vel− genomic sequence has been deposited in GenBank (accession number KC152643).

(e) Genomic sequence alignment of a 745 bp fragment of *SMIM1* spanning exons 3 and 4 compared with the same region sequenced from Vel- individuals. The exons are highlighted in gray. The differences between the sequences are indicated by asterisks; the initiation (blue) and stop (red) codons are underlined.

(f) The predicted nucleotide and amino acid sequence of the extended open reading frame in the mutated *SMIM1* sequence. Gray indicates the SMIM1 amino acid sequence until the frameshift. Thereafter, the sequence differs and transmembrane prediction analysis (**Supplementary Table 5**) does not indicate the presence of a transmembrane domain.

Supplementary Figure 5: RACE on Vel+ blood samples

5'- and 3'-RACE experiments revealed variations compared to the *SMIM1*-mRNA reference sequence (NCBI NM_001163724). An unannotated exon 1 of 19 bp was identified spanning 18 bp upstream of the original start site, and including the first nucleotide of the reference sequence, rendering the original exon 1 obsolete. The 3' end was found to be 26 bp shorter than the reference. No discrepancies were found in the remaining sequence (not shown). The erythroid cDNA sequence has been deposited in GenBank (accession number KC152644).

(a) 5'-RACE. Top sequence is the *SMIM1*-mRNA reference sequence (gray) plus the 18 bp located directly upstream in the genome (black). At the bottom is the sequence identified using 5'-RACE. Blue boxes: Exons 1 and (start of) 2. Red box: 5'-RACE adaptor added during the experiment only to transcripts with an intact 5' cap. **(b)** 3'-RACE. Top panel: 3' end of *SMIM1* reference sequence. Bottom panel: Sequence identified by 3'-RACE. Blue boxes: End of exon 4 and adaptor. **(c)** Full sequence of the characterized wildtype *SMIM1*-mRNA (gray = consensus open reading frame; blue = start codon; red = stop codon).

Supplementary Figure 6: *SMIM1* expression in normal human tissues

This figure illustrates the expression of *SMIM1* across different human tissues, as measured on Affymetrix U133Av2 microarrays (probeset 230840_at). Microarray profiles of normal tissues were generated by Roth *et al.*¹ (data from the NCBI Gene Expression Omnibus, accession no. GSE3526). As positive control, we used microarray profiles of CD34+ hematopoietic progenitors being cultured towards red blood cells (generated by Keller *et al.*²; GSE4655; see also **Supplementary Fig. 2**). All data were quantile-normalized per array to a log-normal distribution. Blue indicates average expression values with min–max error bars. Consistent with **Fig. 2** and **Fig. 4**,

the highest *SMIM1* expression level was observed in bone marrow (where the expression level was on par with that observed in erythroid cultures). Among non-hematopoietic tissues, salivary gland and testes exhibited the highest expression levels.

Supplementary Figure 7: Predictive analysis of potential O-glycosylation sites in SMIM1

Despite the presence of several extracellular serine and threonine residues (blue), the predictive values for all residues lie under the threshold determined by the prediction tool NetOGlyc 3.1 (<http://www.cbs.dtu.dk/services/NetOGlyc>), suggesting that SMIM1 may lack O-glycans. However, we note that some of the peaks in the above diagram are quite close to the threshold. This may indicate a theoretical possibility that SMIM1 may carry minor O-glycans on certain Ser/Thr residues after all. The human O-glycoproteome has recently been shown to be more complex than previously realized and even the best prediction tools may reveal less than half of all O-glycosylation sites used¹. Thus, future studies will need to address such potential O-glycosylation.

The predicted transmembrane region (**Supplementary Table 5**) is underlined.

Supplementary Figure 8: Genotyping assays

Assays to determine Vel genotype were designed (primers in **Supplementary Table 7**; used at 10 pM unless stated). Details of PCR assays are available upon request. **(a)** Allele-specific PCR (ASP): gDNA was amplified with primers 388588int2f (1 pM), 388588int3R2 and either 388588wtex3f or 388588mutex3f. An internal control band was provided by the amplification of a 460 bp (wild type) or 443 bp (mutant) product. Allele-specific bands of 266 bp (wild type) or 249 bp (mutant) were specifically amplified by their respective primers. **(b)** PCR-RFLP: gDNA was amplified with primers 388588int2f and 388588int3R2. The products were digested with *StyI* at 37°C for two hours and analyzed by agarose-gel electrophoresis. The restriction site was abolished in the mutated sequence. **(c)** Gene-specific PCR: gDNA was amplified with primers LOCex3fscreen and LOCex3rscreen which flanked SMIM1 exon 3. Allele-specific PCR products of 178 bp (wild type) or 161 bp (mutant) were discriminated based on size by agarose-gel electrophoresis.

Supplementary Figure 9: Inhibition of anti-Vel

Inhibition tests were performed using synthetic SMIM1 peptides 1–4 with two examples of human anti-Vel. Doubling dilutions of the antibodies were prepared in 1 % BSA/PBS, and 25 μ L volumes of diluted plasma and peptide solution (0.1 mg/mL) were mixed and allowed to incubate for 45 minutes in a microplate at room temperature. The mixtures were tested by hemagglutination with Vel+ RBCs and the reactivity determined as a titration score¹. While tests with individual peptide solutions did not show an effect, a pool of the four peptides demonstrated partial inhibition. Ctrl = 1 % BSA/PBS dilution control; PP = peptide pool.
